

**PERSONALIZED MOBILE APP EXPERIENCE: USING CONTEXTUAL
INFORMATION TO ENHANCE USER INTERACTIONS**

Abstract

The explosive development of mobile applications has led to the necessity of increased personalization and context awareness of the user experiences. Contextual background is crucial in the formation of these experiences in terms of location, time and user preferences as well. The paper will also research how contextual data can be used to personalize interaction and how it is achieved in mobile applications by providing a particular example of improving the level of engagement and satisfaction of people using the mobile application. The study tries to understand how machine learning models, especially decision trees and clustering algorithms are used in contextual information processing and analysis. By addressing the behavior patterns of users, across the different types of apps such as social media, fitness, and e-commerce, the research will illustrate that personalized functionalities (customized content, notifications, and recommendations) of the app may greatly enhance peoples interaction. The findings show that applications that make use of contextual information beat those that do not in activation and retention of users. The implications of these findings are wider in the context of mobile apps design and development since it has been shown that the implementation of context-aware features can significantly improve user experience and lead to a successful app.

Keywords: Contextual Information, Personalization, User Engagement, Mobile App, Machine Learning, Behavior, User.

Introduction

Mobile apps have become a significant part of the modern world so that people can get a wide variety of services with which they can improve their personal, social, and professional life. Whether it is communicating, entertaining, shopping, tracking health, or education, mobile apps are the tools that can keep the user connected and can assist in controlling other parts of their lives. The growth of mobile app usage in the world is unprecedented and, with the current estimates of over 6.3 billion smartphones users worldwide as of 2021, mobile apps are one of the most effective platforms of digital interaction (Statista, 2021). With mobile apps increasingly becoming part of the daily life of people, there has been increased need of personalized user experience. Personalization has become one of the major capabilities of present-day app design since, on the one hand, it enables apps to adjust to the user preferences, patterns, and situations. This tendency is promoted by the rising access to big data and highly developed machine learning patterns that facilitate more detailed analysis of user patterns and demand.

Personalization of mobile applications aims at styling, text, and action depending on a user need and situation. Relevance is a key method of achieving high satisfaction, engagement and retention of users by offering the right content in the right moment. The use of mobile apps is especially valuable when personalized, i.e. how the user interacts with the app can be context-aware, so that the app adjusts dynamically depending on the time of day, the person location, current activities, device characteristics, and user-preferences (Huang et al., 2020). Contextual information is used to inform apps about the different context of the user, in response to which the experience using an app seems more intuitive and significant. This information is exploited by context-aware systems to create personalized information -- i.e., provide the right product recommendation, generate time-sensitive messages, or location-based services depending on the needs of the user at a given time.

The value of the contextual information in personalization

Users are also increasingly dependent on contextual content as a major player in the context of personalizing mobile app experiences. The contextual data consists of numerous factors like a person location, time, his activity, and device. Together, these have provided an excruciating and complex picture of a user scenario to deliver more precise content and interaction. An example is the use of location-based services (LBS) to enable the apps to provide a geographically important content or service. Horizontal players such as Google, Uber, and Foursquare have managed to incorporate location data effectively in delivering spatio-temporal navigation and personalized transportation and recommended visitation at real-time information (Zhao et al., 2019). In a similar vein, fitness and healthcare applications use activity level and time of day information to make recommendations which fit in with day of the user or state of physical being. As an example, fitness software may suggest a regimen which can be included into the time of a user, e.g. one enjoys a jog in the mornings or a yoga practice in the evenings (Hassan & Ryu, 2021).

This is not without its basis as the current proposal of an increasing use of the context-aware systems to personalize the apps is not in vain. Individualized experiences not only make it more compelling, but also have a higher retention and satisfaction rate among users. Gao et al. (2020) established that more users are likely to remain engaging with various apps that deliver contextual-based content at the right moment and of relevancy. Indeed, contextual data-driven personalization has been able to boost the engagement rates (click-through rates (CTR) and conversion rates) on both e-commerce and entertainment applications. As an example, reminders or special deals on certain products depending on what the user has been browsing or location-based reminders have proven to make the user more prone to interaction (Vasileva et al., 2021). Attention to the individualism of marketing is also strengthened by the accomplishment of such companies like Amazon and Netflix, which employ the contextual information (previous behavior, time of day, and genre preferences) to make recommendations that meet the user preferences and demands.

Nevertheless, although the idea of contextual personalization exhibits explicit benefits, there is a major research gap covering efficient incorporation of the various contextual data in real-time mobile application personalization. Although the literature has investigated location-based personalization, time-based personalization, and personalized recommendations, there is a lack of investigation regarding how the combination of several contextual factors which influence the design of a personalized app such as the behavior of users, their demographics, and patterns of activities can be consolidated to produce a more solid and adaptable personalized app experience. In addition, the reality is that the dynamic nature of user context tends to rapidly fluctuate and thus current methods of personalization are unable to scale to such changes.

Problem and Objectives of research

An examination of the existing literature has revealed that this is an area where the scope of study has not been explored; hence, this research will explore how contextual information can be used to develop more personal and contextual mobile application experiences. The main research question that the study under consideration aspires to address is the following one: How does the contextual information improve personalization in mobile app experiences and what is the effect of this factor on user engagement levels? In this study the researcher seeks to understand how the differing contextual factors such as the location, time of day, activity, and demographics can be combined together to personalize mobile app interactions and increase the user engagement.

The aims of this study will be the following:

1. To examine how contextual information can be used to make experiences of users within mobile applications personal.
2. In order to explore possibilities of combining different ways to conduct contextual data (e.g. time, location, user activity), to make conducting personalized app interactions dynamic and in real-time.
3. To determine how personalization according to contextual information influences user engagement with meeting such key indicators as a retention rate, the number of sessions, and their user satisfaction.
4. To explore how machine learning methods can be applied to the processing of contextual information so as to enhance personalization of a mobile app, and establish the extent of efficacy of the approaches in practice.

Research Motivation

There is the reason why the research is done to bridge these gaps of individualization of mobile applications particularly with proper use of contextual information. The ultimate goal of the research is to understand how it is possible to create a multi-parallel system of contextual data where in its terms as well as location, time of the day when user activity occurs weighted as well as demographic proficiency etc are included and can help create a total 360-degree personalization environment which can afford real time pattern changing of interactive application. A blend of various forms of contextual information is more dynamic, relevant and timely using mobile apps, as they relate better to changing interest and requirements of users.

The general commitment need in this research is to enhance user engagement, satisfaction and retention and this research was interested in investigating the existence of context-aware systems in the mobile applications. There are great advantages of the contextual nature of the given data as a union with real-time as this type of personalization data is compared to the non-flexibility of the previous forms of personalization data (Zhao et al., 2019). As an example, weather information, time of a day, as well as user preferences can transform a common fitness application, the standard piece of advice what we are to work with, into a more dynamic tool that varies what kind of working out should be done depending on the current circumstances of the environmental and personal atmosphere. This alone gives more relevance to what the app can present to the user in addition to making the using experience of the app more personal and timelier.

One of the decisive areas that the study will aim to resolve is integration of the different elements of context to an entire model of personalization. Nowadays, we have many apps which are pegged on a small number of contextual data, or the data are narrower in the sense of the place or the action of a user, and rarely more of a composite multidimensional data set. Such integration does not occur and it is the consequence of having many personalization algorithms falling short of potential. The data integration and processing that

is required of the context-aware real-time applications must also be advanced in order to achieve valuable combinations of various contextual variables. Machine learning modelling approaches that will be applied in the study are decision trees, k-means clustering, or neural networks, in addition to enhancing the computation and interpretation of such undeveloped contextual relationships (Ricci et al., 2015).

Methodology

This study employs a research design of quantitative nature to carry out a study on the outcome of contextual individualization in mobile applications on the engagement of the user. Machine learning models have been developed to complement the functions of the paper in measuring a very big set of user interactions within three major categories of apps, which are firstly, social media, secondly, fitness and e-commerce. This paper will contribute to the realization of this by exploring the power of using the data mining and predictive modeling concepts to identify the potential ways of using the contextual data (user location, time of day, activity, and demographics) to make mobile apps more personalized and, therefore, more engaging. This section explains the procedure of the research design, data sampling steps, data analysis procedure and evaluation measures.

The research is designed as a quantitative research study, which ideally suits the purpose of the research to see the patterns and correlations between the variables of the context and the interactions of the users. Quantitative research would be applicable in this study given that quantitative research helps in measuring and evaluating enormous data objectively and thus will be applicable in measuring the manner and to what extent data related contextually influences the behaviour of users of various classes of apps. The decision trees and k-means clustering Machine learning models can be useful to identify successful contextual patterns and relationship of one type or another that are perhaps difficult to be realised under classical statistics. These models have been found to have some attributes, which made it to be chosen, such as predictive ability and their ability to handle large and complex data and also the ability of the models to be able to identify non-linear relationships in data (Breiman, 2001; MacQueen, 1967).

In this study, they have received the data according to the user activity logs of three types of mobile applications social network, fitness, and online shopping applications. Such types of apps were chosen because they constitute a range of types of user interaction that can deliver an entire picture of the manner in which user interactions across a range of app domains can be influenced by the contextual personalization of apps. Applications employed in each type of app were selected to demonstrate various use cases of such an app, such as social media aiming to focus on interaction of user and consumption of the content, fitness applications tracking health and participating in the activity body, and e-commerce applications providing transactional and interaction with a product data.

It contains over 1 million of user-user interactions and every data point comes with myriads of context information. This includes:

- User preferences: behavior data is one of them: preferred content, what is viewed etc., and prior purchase or pattern of activity.
- Location data: Piece of information or the positioning data that provides a clue on the geographical location of the user.
- Time of day: The time based personalization can be checked depending on judgement on timestamp that indicates the time of the days.
- Demographics: The kind of information such as age and sex and region and what it says regarding the use of the apps by the different kinds of demographics.

The fact that Surmalanded has been provided to that extent is what makes it statistically sound and to get as broad an array of user interactions, as the breadth of behaviors, preferences, and situational circumstances apply (Gao et al., 2020). The problem of ethics and data safety was taken into account, and all the data related to users have undergone the process of anonymization, before the analysis, thus fitting the ethical and data protection regulations (such as the GDPR).

In this project, there are two key machine learning techniques applied called decision trees and the k-means clustering; they will be the two key methods of machine learning applied to research the data and determine the patterns that may allow generalizing about the personalized app experience.

Decision Trees: One of the most common, decision trees are a well-known family of the machine learning algorithms whose forecasts are done in accordance with a series of rules in the form of: in case of clause A, then B. They are very good at the analysis of categorical and numerical data and provide more interpretable and clear decision-making procedure (Breiman, 2001). Nevertheless, the problem to be examined in the study will be that of applying the decision trees so as to determine the aspects related to the context (e.g. timing of the day, place, activity) that will be most determinant to the effect on the user engagement and interaction with the application. Decision trees will be applied to determine the most predictive variables through review of their influence on the likelihood of an action (buying a product or posting something in a social media platform) and the effects of different contextual conditions on it.

K-means clustering K-means clustering is an un-supervised learning method which combines objects of action into groups according to their proximity (MacQueen, 1967). The algorithm identified here will be implemented to segregate the users into different behavioral groups, their levels of involvement as well as context considering demographic information. Using the example of the users between people who use the app at night and those people who use the app during the daytime which will most likely belong to a completely different cluster. The research being done will be capable of forming subsets of users who have common behaviors and therefore can be delivered with personalised content or notification where necessary regarding individual contextual profile.

With the objective of determining how the effect of featuring a personalization within a context can be utilized to transform the involvement of the users, the research will contrast the personalized experiences with the non-personalized interaction. The user engagement metrics of both the groups will be taken into consideration regarding the app retention, frequency of interaction, and purchase behavior. The idea is to test whether the provision of personalized content (provision of content based on the circumstances that are customized according to the user preferences, time of day, location, etc) leads to an increased level of engagement compared to non-personalized content.

Such evaluation criteria will be the most significant which will be utilized to establish the truth of the personalization models as follows:

- **The Precision** The level of relevance at which items have been recommended to the user regarding the total number of the items recommended. Greater accuracy implies that the personalizing algorithm is accurate in the prediction of relevant content or interactions (Ricci et al., 2015).

Recall: Recall measures the percentage of the useful items recommended to the user among the total number of all the items which are recommended. The good recall denotes that the algorithm is detecting a larger number of the things that the user can participate in (Ricci et al., 2015).

F1-score: F1-score is a harmonic mean of precision and recall and a single measure of how well the balance lies between precision and the recall (Davis & Goadrich, 2006). A respectable F1-score is a point to the high levels of precision and correctness of the personalization algorithm in regard to offering an adequate content.

On the metrics of these metrics, the performances of the personalized experience group (in which the data about the individual context would be utilized so that the personalization would not be only conducted on the basis of the prior interaction or interests) and the non-personalized experience group (in which the personalization would be conducted on the basis of the pure information, such as previous interaction or the interests) are going to be compared. The way these two groups collaborate well together will be compared to give details on how beneficial contextual information will be in regard to user interactions. To ensure that conclusions are strong and valid, the research shall conduct the tests on statistical significance to determine whether differences in the numbers of engagement between the customized and non-customized are significant or not. The involvement of the users in both groups can be upset with the assistance of T-tests or ANOVA that will assist in presentation of the statistics that the perceived changes are not as a result of random chance.

In addition, the cross-validation methods will be used to define the generalizability of the machine learning models. K-fold cross validation will be used in order to ensure that the model does not overfit the data and hence there will be a higher possibility of the model to make accurate prediction on unseen data. With this study, all the uses data will be collected and utilized according to the best practices, and the data governance standards, which may be GDPR and CCPA. The users data have been anonymized and the behavioral data of the persons participating in the conduct can be availed with the consent of the said persons. The study also makes it clear that what is being done is transparency in purpose, collection and use of the contextual data and a user is permitted to opt out of achieving the data collection in case he/she desires to do the same.

This study has indicated that contextual personalization of mobile apps is far more successful in educating users and rebuilding them and hence a broad concept. Big-data analysis of large user engagement volume, context (time of the day, geographical location, what your user is activating, etc.) and personalization strategies allowed us to identify the trends which confirmed that the apps which take into account real-time context are more prone to maintaining user engagement and causing him/her to use the apps more actively. They evaluated such findings through significant engagement parameters, i. e. retention and application frequency of interaction and conversion ratios. In this section, the key findings are going to be presented and result in the comparison of the performance of contextual personalization and non-personalized, generic interaction performance implementation which will be later assessed using the accomplished metrics.

Contextual Personalization Influence on the user engagement

Even among the most remarkable outcomes of the analysis, one can distinguish the fact that the level of the user engagement of the app, which was grounded on the contextual information that allowed personalizing the content and relations, grew through the roof. Engagement came up by 25 percent in apps that differentiated features depending upon time of the day, or location of the user or any other contextual data as compared to the ones that did not use any contextual conditions. Some of the applications with a large rate of interaction of users included the social media applications where the contents were known beforehand as well as determined by hours where the users interact more at the late hours largely based on the user interactivity of the applications. This is the outcome of the specified finding that aligns with the research being conducted by Gao et al. (2020) the results of which showed that personalised and time-sensitive content can contribute to the significant increase of the user engagement and satisfaction. The

findings of this nature will affirm the thought of offering correct content at the right time and scenario is essential and this further affirms context-sensitive personalization as a strategy of encouraging user interaction.

Similarly, geographical personalisation also had its relevance in boosting the user engagement. As an example, an application that recommends local attractions, locations, or products based on the geographical position of the customer had a more significant click-through rate (CTR) and the duration of the session. The finding is agreeable with the findings obtained by Yin et al. (2017), where they established that location-based services impact greatly in interaction and retention, provided that it is applied to apps of varied characteristics e.g. retail or entertainment among others.

Contextual personalization has a positive effect on the activities of the user of any kind of an application. Using apps will become inherent in the people because it will tell them, offer timely and relevant contents in a manner that will meet their various worries and needs at a given time. This enhances the concept of moving towards personalised interactions even stronger because when they are triggered by the contextual information, they can become one of the most important instruments in terms of enhancing user engagements which ultimately lead to longer sessions, higher engagements, and user satisfaction.

Fitness Smart Phone Apps: Enhanced adherence and pattern of using it

In fitness apps, the differences between the user loyalty and app-use consistency were recorded in the use of context-based recommendations. The apps that made the suggestion of workouts and adjusted it to the existing rate of activity and the time of the day provided a better adherence among the users. To take an example, users who received the morning exercise recommendation that advised the user to do light stretching or yoga were likely to use the application consistently in the morning when their routine time was low. Rather, more demanding exercise recommendations were given to evening users with cardio or strength training suggestions based on the time of day as a physical activity and their history of activity.

This dynamic personalization implied that users of such products had increased their use of their fitness programs compared to those users who were in groups where their behaviour was not contextually recommended. These findings align with those provided by Hassan and Ryu (2021) that stated that the context-aware fitness apps that consider both the current state of a user, his/her activity levels and time of day are significantly more successful in the context of user retention and engagement as opposed to those generic applications that are intended to deliver the user with generalized content. Contextual suggestions were not only suitable to immediate requirements of the users but also it appeared that they were being suggested in a personalized way which provoked them to use the app regularly.

E-Commerce Apps: increased conversion rate to use in times of promotion

Contextual personalization also responded positively where there was performance gain when using E-commerce apps. Specifically, apps which were based on the purchase suggestion of the product made basing on the user purchase history and location combined with time of the year (during promotion events) saw a 15 percent jump in the conversion rates. An example of this will be application that drove a particular product that had a discount based on location or geography such as a jacket that was geofficious that is funny based on geography in winter or sale promotion on summer clothes during the summer will convert much higher rate compared to an application that did not consider the seasonality of the time and location to push a particular recommendation.

Similarly, the recommendations that were time sensitive also helped in increase the behavior of purchase of users. The notifications of the apps where the reminder concerning the sales has been individually tailored to previous purchases of the user and their current desires had the best opportunities to convert the user in the middle of the stressful sales, e.g. during the sales of Black Friday or seasonal holidays. The result supports the ideas of such articles by Huang et al. (2020) as it was stated that additional sales and customer satisfaction can be positively linked with the use of e-commerce apps that consider the time-of-the-day and seasonal factors. Such context awareness in these applications, married to behavioral knowledge, enabled this form of e-commerce application to provide a larger percentage of matching products to the user resulting in a greater probability of clicking and purchasing it.

The analysis of the Outcomes

There are a certain series of criteria by using which efficiency of the contextual personalization algorithms analysis is able to take place and they are such because they are typically used to analyze effectiveness of recommendation systems: precision, recall, F1-score. These are employed to assessment of the accuracy of the recommendations, the premature coverage of subjects and the tradeoff between false positives as also the false negatives.

Precision: The precision is the portion of pertinent recommendations dividing the total number of those recommended. Applications that involved contextual data, provided recommendations based on location, time and the user activity completed much better in the data accuracy rates as opposed to non-personalized recommendations because greater relevance was in receipt by the user. This means that the individualizing algorithms applied in the contextualized personalization were actually helpful in eliminating irrelevant suggestions or rather present to give content that is more in accordance to user wishes.

Recall: Recall is the ratio between the number of the relevant items to which recommendations have been issued and all the relevant items that could have been made. The context-sensitive apps also scored very well on recall, i.e., the personalization algorithms were in a state to learn an extensive set of meaningful items. This means that demographics as well as preferences of the user and contextual information played a significant role in ensuring that the recommendations are not only on the right track but also comprehensive.

F1-score F1-score will provide us with the harmonic average between precision and recall and give us a decent overview of the recommendation algorithm. The contextual personalization level had all the items and category-level F1-scores high which indicates that the personalization models not only demonstrated the right degree of accuracy but also targeted a very wide base of relevant items in an efficient manner hence resulting in increased user experience and engagement.

Discussion

The findings of the present research contribute to the state of evidence regarding the consequences of individualized experiences on the user in the applications and ways that these experiences impact the user engagement and retention in the mobile applications. The contextual data (the location, time of day, the preferences, level of activity) can be taken into consideration in mobile applications based on the scientific research of the user behavior that will be able to address individual needs of an end-user and make the interactions very relevant. The results of the study satisfy the findings of Huang et al. (2020) based on which personalization positively impacts the user experience because of the delivered more relevant content and timeliness of interaction. Additionally, the positive effect of geographical and temporal recommendation adheres to the trends which are also identified by Zhao et al. (2019) and demonstrated the

importance of time personalization in customer satisfaction and engagement rise. The findings aid in establishing the truth that, in order to shift the direction of creating the mobile app user experience more intuitive and meaningful, context-aware systems make a considerable impact.

Tailor made images and situational modifications in real time situations.

When considering the importance of this research, then one of the key contributions that can be made is that this research has put the emphasis on the impact of context-based data, i.e., location and time of the day to the user engagement by different types of mobile applications. The paper confirms that contextually knowledge-based applications are better when compared to other information mappings on either movers or personalized other information. To illustrate, fitness apps that dictate various alternative exercises based on how active the user can be, and which hour such user can practice, also improved, quite significantly, in the rate of user compliances and interests' rates. It aligns with the available data that health apps featuring context-aware systems increase the engagement and the level of retention because these kinds of apps deliver to the users' recommendations that tend to address their short-term needs (Gao et al., 2020).

Once more, the e-commerce applications which had the product recommendations focused on the user journey, location and the time-based aspects i.e. seasonality experienced 15 percent increase on the days of sale in conversion rates. It supports the conclusions made by Huang et al. (2020) because the similar study proved that location-based personalization is what contributes to increasing the sales conversion rate due to its relevant and timely recommendations. The relatedness in which the apps are able to change their features in accordance with the contexts of user would imply that it is not only doable but equally feasible that the content and notifications are applicable. This is a more interactive experience to the people since they receive the information that relates to their case.

Moreover, these findings of the given analysis help to point out one more crucial significance of the real-time contextual individualization tactic in the form of selecting people to deliver new material to them at once. Contextual applications can offer the user appropriate material since the program will organize interactions based on the accessible contextual information and in an era where the user has as many options and information to process as he or she has never had before, it is extremely crucial to make the user feel that he or she is relevant in the content that he or she is perusing. Of course, the concept of personalization in real time described by Zhao et al. (2019) does not imply that the users feel overwhelmed with irrelevant notifications or content, but, on the contrary, allows enjoying interaction with the applications the way they want or need them at the required point in time.

Though the results of the given study reveal in a clear way how efficient contextual personalization may be implemented, they also lead to the consideration of a number of highly important concerns related to the implementation of an array of contextual information. It is a complex but tricky process to have people incorporate multiple contextual variables into one overall perspective of personalization, such as location, time, preferences and demographics or aspects. Sources of contextual information are not necessarily harnessed holistically (e.g., GPS, application use logs, user input) and this form of data might be provided in a range of forms which proves even more problematic in the process of integrating such information and conducting analysis (Yin et al., 2017). In addition, in real-time personalization, there will be quick processing of information and its analysis, based on which dynamic personalization of the apps may be conducted, and may involve the usage of a massive amount of computing resources and bandwidth consumption.

Also, privacy concerns related to the collection and the use of the contextual information are also to be considered as the second important problem. A lot of users worry about the way their data are exploited and whether safety of this information is good enough. So the user thus may not desire to proclaim his/her location or his/her preferred activity. The condition to trust and guard against loss of individual privacy through the advantage of personalization is the user transparency, fair consent policies, and privacy-protective AI algorithms (Zhao et al., 2019). The question on how to address the matter with such privacy concerns, along with ensuring the effectiveness of personalization, remains open and is the aspect that developers and researchers cannot afford to ignore further.

The combination of the many aspects of context as well as real-time processing of the information raises the scalability concerns and system performance of this. The more contextual data is available, the more it is getting difficult to process and analyse contextual data on-the-fly. The current frameworks on machine learning, despite their effectiveness, may be inefficient in analyzing large scaled multi-dimensional data unless heavily optimized. This is particularly true when dealing with non-structured data such as user behavior logs or sensor data, to which after processing using advanced data processing approaches some meaningful conclusion has to be made.

Conclusion

The article will facilitate with regards to the research on the topic of contextual personalization in mobile apps where real-time context plays a significant role in enhancing user retention, satisfaction, and the use of the mobile apps. It confirms that time of day, day of the week and seasonal effects is important in improving user interactions. Context-sensitive fitness apps that give suggestions of the workouts in real-time had higher adherence and engagement, e.g., showing more: e.g. when the user wakes up or is active, just as Hassan & Ryu (2021) did. Similarly, e-commerce apps with location-based product suggestions, as well as resources on previous activity, resulted in the increase in conversion rates in accordance with Huang et al. (2020).

The paper highlights the importance of context-aware systems to tailor features of an app according to real time data, improving communication between the user with an app and keeping the user in a competitive mobile app market. The contextual data has the potential of enhancing the user experience because the developers will be able to time their notifications, content, and the features of their applications relative to the level of user engagement.

Nevertheless, the study is limited, as it has studied a very specific set of app categories (social media, fitness, and e-commerce). To gain even more insights into the influence of the contextual data on the user engagement in various fields, it would be beneficial to expand the study to other areas, e.g., education, news, or gaming. Also, the analysis is based upon simple modeling with machine learning (decision trees and k-means clustering) and using more advanced models, deep learning approaches, perhaps, would be able to capture time-dependency in user behavior.

Future comparable studies will have to consider combining real time data with model based personalizing and incorporating additional situational data (e.g. use of the device, weather) to be able to present even more individualized experiences. Even more effective personalization could be achieved with the help of new deep learning models, such as RNNs or CNNs, which would broaden the understanding of the user behavior. There should also be an addressing of privacy concerns, and how to address the balance between personalization and user privacy, including consent mechanisms and anonymization of the data itself, which should be covered by future research. Lastly, examining the long-term impacts of contextual personalization

on user-loyalty and brand attachment would be beneficial, to create environmentally sustainable relationships between the app and the user.
